Abstract: The aim of the present work was to determine whether Dermacentor reticulatus (Fabricius), tick species common in eastern Poland could be infected with Toxoplasma gondii (Nicolle et Manceaux, 1908). A total of 664 unfed D. reticulatus ticks were collected from six localities of Lublin province (eastern Poland) within the framework of study for the presence of bacterial, viral and parasitological infections, with use of PCR and confirmed by sequencing analysis. The prevalence of T. gondii DNA of B1 gene in the total examined D. reticulatus ticks was 3.2%. The infection varies greatly depending on the locality of tick collection (0–16.7%). Preliminary identification of clonal type (I or II/III) by Restriction Fragments Length Polymorphism PCR (RFLP-PCR) with use B1 gene showed that all isolates of T. gondii belonged to type I. RFLP analysis using genetic markers SAG1, 5'-SAG2, 3'-SAG2, SAG3, and GRA6 on B1-positive samples showed that only a single isolate proved to be type I with all five markers, another type was classified to type I according to four markers, while another five isolates had only type I alleles at GRA6, which cannot be regarded as type I confirmation. It must be pointed out that the used DNA isolation method by boiling with ammonium hydroxide enables to receive the total DNA from ticks, but may not be quite suitable for genotyping. In conclusion, this study indicates that besides Isodes ricinus (Linnaeus), also D. reticulatus should be considered as a potential vector of T. gondii. The presumption of tick-borne transmission as an alternative pathway of disease spreading could well explain the high prevalence of toxoplasmosis among the herbivorous mammals and birds. However, this hypothesis needs verification by further experimental and ecological studies.

Keywords: toxoplasmosis, vectors, ticks, Poland, PCR, RFLP-PCR

Toxoplasma gondii (Nicolle et Manceaux, 1908) is an obligatory intracellular parasitic protist within the phylum Apicomplexa, family Sarcocystidae – Perkins et al. (2000). Until recently, the sexual reproduction of the parasite has been observed only in the intestine of felids, which are definitive hosts of T. gondii, while a large number of other mammalian and bird species have been identified as intermediate hosts, which are commonly infected with this protist. In humans, the parasite causes toxoplasmosis, a usually asymptomatic zoonotic disease which, however, may pose a severe medical problem as a congenital infection causing cerebral and ocular damage in newborns and as an acquired infection in immunocompromised individuals, such as AIDS patients (Dubey and Beattie 1988).

Three main genotypes are responsible for the majority of human infections: type I strains are associated with severe or atypical ocular toxoplasmosis in immunocompetent adults and are represented in congenital infections; type II responds for most clinical toxoplasmosis cases in immunocompromised patients and has been also isolated in cases of congenital toxoplasmosis; type II and III strains are often isolated from animals. Additional genotypes, such as genotype ‘A’ (atypical) are also recognised, but appear to be less common (Howe and Sibley 1995, Dardé 1996, Grigg et al. 2001, Miller et al. 2008).

Oral transmission by consumption of raw meat containing parasite cysts or by consumption of food and water contaminated with cat faeces containing T. gondii oocysts is regarded as the main route of primary infection. However, this route hardly explains the common occurrence of T. gondii in a variety of hosts, such as herbivorous mammals, wild rodents and birds that are unlikely to contract primary infection orally with meat or cat faeces. Thus, some additional routes of transmission suggested by earlier authors and partly forgotten should nowadays be reconsidered, including infection by skin lesions and transmission by arthropods (Derylo et al. 1978).

A number of earlier studies indicated that ticks (Ixodida) may be potential vectors of T. gondii (see Gidel and Provost 1965, Singh et al. 1965). Derylo et al. (1978), provided evidence that the hard tick Ixodes ricinus (Linnaeus) may participate in the transmission of this protist. The presumptive role of I. ricinus as potential vectors of T. gondii has been confirmed by more recent studies carried out by our group with the use of polymerase chain reaction (PCR). The presence of T. gondii in ticks was confirmed by the
detection its DNA in tissues of mice inoculated with the homogenate of *I. ricinus* ticks harvested from the natural environment (Sroka et al. 2003, 2008).

The aim of the presented study was to determine whether Dermacentor reticulatus (Fabricius), another tick species common in eastern Poland, could be infected with *T. gondii*.

**MATERIALS AND METHODS**

**Collection of ticks.** A total of 664 unfed *Dermacentor reticulatus* ticks (378 females and 286 males) were collected during the spring season (between March–May in 2011 and 2012) in the following localities situated on the territory of the Lublin province (eastern Poland): Suchawa (locality A), Sobibór (locality B), Poleski National Park (locality C), Ostrów Lubelski (locality D), Nielisz (locality E) and Wilków (locality F). Ticks were collected by dragging a woolen flag over the lower vegetation and litter along the paths and edges of deciduous and mixed forests. Only adult ticks (females and males) were collected. Collected ticks were placed alive in glass tubes for further investigation.

**DNA isolation from ticks.** Total DNA was isolated from the adult ticks separately by the ammonia method (Rijpkema et al., 1996). The concentration of DNA in the isolates was determined with a NanoDrop ND1000 Spectrophotometer (USA). The determined DNA concentrations ranged 520–672 ng/µl for males and 670–878 ng/µl for females of *D. reticulatus*. The obtained lysates were stored at -20 °C for further examination.

**Detection of *Toxoplasma gondii* DNA (B1 fragment gene) by PCR and RFLP-PCR methods.** Detection of *T. gondii* DNA, based on the amplification of 35-fold-repetitive gene B1 fragment in the two following nested PCR reactions, was performed by a method according to Grigg and Boothroyd (2001). Each PCR reaction (50 µl of total volume) contained 1.5 U Taq DNA polymerase (Qiagen, Valencia, California, USA), a set of primers: Pml/S1 and Pml/AS1 or Pml/S2 and Pml/AS2, dNTPs in a final concentration of 0.1mM, nuclease-free water and 5 µl of isolated DNA. The amplification was carried out in a C1000 Thermal Cycler (BiOrad). Positive and negative controls for each reaction was used as mentioned above. Products of amplification were identified in 2% agarose gel after electrophoresis in standard conditions and staining with ethidium bromide solution (2 µg/ml). Amplification products were digested by restriction enzymes, according to the protocol of the enzymes producer (Thermo Scientific). RFLP patterns were identified in 2.5% agarose gel.

**Statistical analysis.** Data were analysed by χ²-test, with the use of STATISTICA for Windows v. 5.0 package (StatSoft Inc., Tulsa, Oklahoma, USA). The value p < 0.05 was considered significant.

**RESULTS**

The prevalence of the *Toxoplasma gondii* DNA of the B1 gene in *Dermacentor reticulatus* was 3.2% (Table 1). No significant difference could be found between the prevalence of infection in males and females (respectively, 3.5% and 2.9%, P = 0.662). In contrast, the infection varies greatly depending on the locality of tick collection and this association was highly significant in males (χ² = 173.22; P < 0.000001), females (χ² = 96.03; P < 0.000001) and total ticks (χ² = 100.43; P < 0.000001). This dependence was mostly due to the high prevalence of infection in two localities (Wilków and Sobibór), accounting for 14.3–16.7%, whereas prevalence was much lower in the remaining four localities, ranging from 0.0–2.7% (Table 1).

The sequence analysis of samples positive for the B1-gene confirmed that the amplified products showed 100% homology with *Toxoplasma gondii* (GenBank: AF179871.1). RFLP analysis on B1-positive samples showed that all *Toxoplasma* isolates from *D. reticulatus* belonged to Type I (not digested by Eco721 nor Xhol).

DISCUSSION

Dermacentor reticulatus is a common tick in eastern Poland identified as a potential vector of numerous pathogens in this area, such as tick-borne encephalitis virus (TBEV) (Wójcik-Fatla et al. 2011), Babesia microti (França, 1909) (see Wójcik-Fatla et al. 2012) and spotted fever group rickettsiae (SFGR) (Wójcik-Fatla et al. 2013). The presented results indicate that besides Ixodes ricinus, also Dermacentor reticulatus should be considered as a potential vector of Toxoplasma gondii, although seemingly with a lower infection rate compared to the aforementioned tick species (Sroka et al. 2008, 2009).

Nevertheless, the presented hypothesis about the possible role of ticks in the epidemiology of toxoplasmosis must be regarded with some caution, because some authors were not successful in isolating T. gondii from ticks collected in natural habitats or in experimental transmission of the infection by these arachnids (Jagow and Hoffmann 1970, Gill et al. 1971). It is also not known which stage(s) of D. reticulatus might be involved in the transmission of T. gondii and how the life cycle of parasites looks in the tick body. In this work, T. gondii DNA was found only in the adult ticks; however, in an earlier study, Derylo et al. (1978) evidenced the transmission of T. gondii by intermittent blood sucking of I. ricinus nymphs, but not larvae and females. In the present study, no D. reticulatus nymphs were found and the natural infection rate of this stage remains unknown and needs elucidation.

Dermacentor reticulatus occurs mostly in eastern Poland, but its range and abundance is steadily increasing and in many localities it is more numerous than I. ricinus – Mierzejewska et al. (2015). This is a three-host tick species, which means that the individual stages (larvae, nymphs, adults) feed on different hosts: larvae on small mammals (rodents and insectivorous), nymphs on small mammals and medium-size animals (such as lagomorphs), and adults mostly on cattle and big wild ruminants (usually on elks), but they could attack also humans (Estrada-Peña and Sore-Schoch et al. 2011, Burrells et al. 2013, Turčeková et al. 2014). However, type I is actually rarely detected in Europe and various studies conducted in animals and humans showed a predominance (~95%) of type II (Ajzenberg et al. 2009, 2010). There is not clear evidence about the relation between disease symptoms and parasite genotypes. Type I isolates are more likely to be involved in severe toxoplasmic retinochoroiditis in human patients; also, atypical isolates often cause severe acute toxoplasmosis in immunocompetent patients (Khan et al. 2005, Su et al. 2010).

In the present study, RFLP analysis on B1-positive samples showed that only a single isolate proved to be type I with all five markers, another was classified to type I according to four markers, while another five isolates had type I alleles only at GRA6, which cannot be regarded as confirmation as being type I. These incomplete results may be due, at least in part, to the DNA isolation with the ammonia method which is not quite suitable for genotyping. Thus, primary classification of T. gondii isolates by RFLP-PCR as belonging to type I must be assumed with caution. The T. gondii strains belonging to genotype I were earlier also found commonly with the use of RFLP-PCR in I. ricinus (Sroka et al. 2008, 2009), but in contrast to the present work, I. ricinus ticks harbored also strains belonging to II/III genotypes and strains preliminary classified as ‘atypical’.

Summarising, the presented results suggest that ticks could be considered as potential vectors of toxoplasmosis. This presumption has been confirmed recently by other studies. Thus, Tanaka et al. (2012), proved experimentally in Japan that the ticks Haemaphysalis longicornis (Neumann) can harbour T. gondii, which suggests that the ticks may participate in the spreading of toxoplasmosis. These authors expressed the opinion that the infection induces in ticks synthesis of the antimicrobial peptide longicin belonging to the group of defensins. In a recent study from Sosnowiec, Poland, a very high percentage (65%) of I. ricinus ticks collected in Silesia (southwest Poland) showed the presence of T. gondii DNA (Asman et al. 2015).

In conclusion, the current study indicates that besides I. ricinus, also D. reticulatus should be considered as a po-

Analysis with the multiplex PCR method showed that the identification with all 5 markers (GRA6, 3’SAG2, 5’SAG2, SAG3 and SAG1) was possible only for a single isolate (a female from Sobibór), which proved to be type I. Another (a male from Sobibór) was classified to type I according to 4 markers (GRA6, 3’SAG2, 5’SAG2 and SAG3, without SAG1). The other 5 isolates (2 females from Sobibór and Ostrów Lubelski and 3 males from Ostrów Lubelski) had type I alleles at GRA6. The primary classification of the T. gondii isolates by RFLP-PCR as belonging to Type I must therefore be assumed with caution.
tential vector of *T. gondii*. The presumption of tick-borne transmission as an alternative pathway for the spreading of the disease could well explain the high prevalence of toxoplasmosis among herbivorous ungulates, small mammals and birds. However, this hypothesis needs verification by further experimental and ecological studies.
