Abstract: Six types of sphaeractinomyxon are reported from the coelomic cavity of oligochaetes collected from the Minho River estuary in northern Portugal. Four new types are morphologically and molecularly described from freshwater species belonging to the genera Psammoreyctides Hrabě and Potamothrix Vejdovský et Mrázek in the upper estuary, thus significantly increasing the number of known freshwater sphaeractinomyxon. In the lower estuary, sphaeractinomyxon types 8 and 10 of Rangel et al. (2016) are recorded infecting the marine oligochaete Tubificoides pseudogaster (Dahl). A single specimen of T. pseudogaster further displayed infection by one of the four new types found in the upper estuary, suggesting the involvement of sphaeractinomyxon in the life cycles of myxosporean species that infect migratory fish hosts. The acquisition of these second hosts is proposed to have allowed the myxosporean counterparts of sphaeractinomyxon to cross environmental barriers and conquer new habitats. Phylogenetic analyses of the SSU rRNA gene reveal the four new types clustering within the monophyletic clade of mugiliform-infecting myxobolids, strengthening the previously proposed involvement of the sphaeractinomyxon collective group in the life cycles of this specific group of myxosporeans. Endocapsa types also cluster within the latter clade, having actinospores that differ from those of sphaeractinomyxon only in the presence of valvular swellings that do not change when in contact with water. In this study, however, one type was found displaying actinospores with and without valvular swellings in the same oligochaete specimen. This overlap in actinospore morphology is given as grounds for the demise of the endocapsa collective group.

Keywords: Myxosporea; actinospore; life cycle; Annelida; SSU rRNA gene; Minho River

Infection of aquatic oligochaetes by actinospores was first reported by Štoltc (1899), who described Synactinomyxon tubificis, Triactinomyxon ignotum and Hexactinomyxon psammoreyctides developing in tubificids collected from the Vltava River in the Czech Republic. In the years that followed this discovery, the acquisition of knowledge of actinosporean infections was relatively limited, due not only to low prevalence of infection, but possibly also because they were thought to have little direct economic significance.

In 1984, however, Wolf and Markiw (1984) demonstrated that the life cycle of Myxobolus cerebralis Hofer, 1903, an economically important myxosporean parasite of salmonid fishes, developed triactinomyxon actinospores in the gut epithelium of the oligochaete Tubifex tubifex (Müller). This discovery led to the demise of the class Actinosporea (see Kent et al. 1994), but simultaneously boosted interest in the study of actinospores as life cycle stages of the Myxosporea.

Until the invalidation of the Actinosporea, six sphaeractinomyxon had been described: S. stolci, S. gigas, S. danicae, S. ilyodrili, S. amanieui and S. rotundum (Caulery and Mesnil 1940, Granata 1923, Georgevitch 1938, Jirovec 1940, Puytorac 1963, Marques 1984). These types were named following the binomial nomenclature system and described mainly based on the morphological characteristics of their actinospores, which were represented in schematic drawings.

In the years that followed, Sphaeractinomyxon types 1 and 2 of Hallett et al. (1997), Sphaeractinomyxon ersei Hallett, O’Donoghue et Lester, 1998 and Sphaeractinomyxon leptocapsula Hallett, Erséus et Lester, 1999 were...
described from marine oligochaetes in Hong Kong and Australia (Hallett et al. 1998 1999), but only S. ersei had its SSU rRNA gene sequenced. More recently, 13 sphaeractinomyxon types were morphologically and molecularly described from marine oligochaetes in two Portuguese estuaries (Rangel et al. 2016, Rocha et al. 2019a). Overall, the implementation of molecular methodologies to the study of sphaeractinomyxon types has revealed a higher biodiversity than expected based on morphology-based criteria. In fact, Rangel et al. (2016) showed that actinospore measurements overlap between different types of this collective group, so that the usage of molecular tools is indispensable for the description of new types. Phylogenetic analyses of the SSU rRNA gene further disclosed a possible involvement of the sphaeractinomyxon collective group in the life cycle of mugiliform-infecting myxobolids (Rocha et al. 2019a), which remains to be proved by either molecular inference or experimental transmission studies.

In the late 1990s, two other collective groups were erected to encompass actinospores that differed from sphaeractinomyxon in specific aspects of their morphology and sporogenic development. The tetraspora collective group comprised types that while displaying the typical morphology of sphaeractinomyxon, developed in groups of four within the pansporocysts, instead of the usual groups of eight. However, recent studies acknowledged this character as too variable to establish distinction between the two collective groups. Consequently, tetraspora was deemed invalid and its two types were transferred to sphaeractinomyxon: sphaeractinomyxon types A and B of Hallett and Lester (1999), formerly classified as Tetraspora discoidea Hallett et Lester, 1999 and Tetraspora rotundum Hallett et Lester, 1999, respectively (Rocha et al. 2019a). These types were described from Australian marine oligochaetes based solely on actinospore morphology (Hallett and Lester 1999), but the first has since then been molecularly reported from its type host.

In turn, endocapsa was erected to encompass actinospores that differed from sphaeractinomyxon only in the presence of valvular swellings that do not change when in contact with water (Hallett et al. 1999). The validity of this collective group was questioned in recent studies (Rangel et al. 2016, Rocha et al. 2019a). Nonetheless, it remained valid and currently comprises four types: Endocapsa rosulata Hallett, Erséus et Lester, 1999 and Endocapsa stepheni Hallett, Erséus et Lester, 1999 from the marine oligochaete Heterodrilus cf. keenani Erséus in Australia (Hallett et al. 1999, 2001); Endocapsa type 1 of Hallett et al. (2001) from immature tubificids, also in Australia; and Endocapsa type of Székely et al. (2007) from the freshwater oligochaete Psammostomum albicola (Michaelsen) in Syria. Molecular data of the SSU rRNA gene are available for both E. rosulata and Endocapsa of Székely et al. (2007).

This study investigated the biodiversity of actinosporean stages infecting freshwater and marine oligochaetes in a northern Portuguese river, from which only one myxosporean species was previously reported (see Rocha et al. 2019b). Among the different collective groups recorded, sphaeractinomyxon was represented by two known and four new types that are described here morphologically and molecularly. The morphological variability found among the actinospores belonging to one of the new types is given as ground for the demise of the endocapsa collective group.

**MATERIALS AND METHODS**

**Sampling sites and morphological characterisation**

Between 2015 and 2016, mud was collected from two sites in the Minho River, northern Portugal. One site was located in the upper estuary, close to the fyke-nets stationed near the village of Vila Nova de Cerveira (41°56’N; 08°45’W). The other was located in the lower estuary, near the village of Caminha (41°52’N; 08°50’W). Mud from the upper estuary was collected using a Van Veen grab sediment sampler with an area of 500 cm2 and a maximum capacity of 5,000 cm3, while mud from the lower estuary was collected manually at low tide.

In the laboratory, oligochaetes were isolated from the mud and kept at 4 ºC, individually placed into 12-well plates containing either dechlorinated freshwater or brackish water (15% salinity), depending on the sampling site from which the mud was obtained. Salinity values at the fyke-nets in the upper estuary are generally below 0.5‰, increasing slightly during dry summer periods. In turn, salinity values in the lower estuary range between 15 and 40‰ throughout the year (see Dias et al. 2016).

All specimens were examined using the light microscope for the detection of actinosporean stages in internal tissues and cavities. Developmental stages and free actinospores were observed and photographed using an Olympus BX41 light microscope (Olympus, Tokyo, Japan). Morphometry was determined from fresh material, in accordance to Lom et al. (1997). Measurements include the mean value ± standard deviation (SD), range of variation, and number of measured actinospores (n). All measurements are in micrometres.

**Molecular methods**

Genomic DNA from infected oligochaetes was extracted using the GenElute™ Mammalian Genomic DNA Miniprep Kit (Sigma-Aldrich, St Louis, MO, USA), following the manufacturer’s instructions. The DNA was stored in 50 µl of TE buffer at -20 ºC until further use.

The SSU rRNA gene of the actinospores was amplified using both universal and myxosporean-specific primers: the 5'-end by pairing the primer 18E (5'-CTG GTT GAT CCT GCC AGT-3') (Hillis and Dixon 1991) with ACT3r (5'-ATT GTT CGT TCC ATG-3') (Rocha et al. 2014) and MYX4R (5'-CTG ACA GAT CAC TCC AAC-3') (Hallett and Diamant 2001); the 3'-end by pairing the primers ACT3f (5'-CAT GGA AGC AAC AAT-3') (Hallett and Diamant 2001) and MYX4F (5'-GTT CGT GGA GTG ATC TGT CAG-3') (Rocha et al. 2015) with 18R (5'-CTA CGG AAA CCT TGT TAC G-3') (Whipp et al. 2003).

PCRs were performed in 50 µl reactions using 10 pmol of each primer, 10 nM of each dNTP, 2.0 mM MgCl2, 5 µl 10 × Taq polymerase buffer, 1.5 units Taq DNA polymerase (NZYTech, Lisbon, Portugal), and 3 µl (approximately 100–150 ng) of genomic DNA. The reactions were run on a Hybaid PxE Thermocycler (Thermo Electron Corporation, Milford, MA, USA), with initial denaturation at 95 ºC for 3 min, followed by 35 cycles of 94 ºC for
RESULTS

Myxozoan survey and overall prevalence of infection of sphaeractinomyxon

During this study, 4,593 oligochaete specimens were isolated from the sediments collected from the Minho River: 4,016 from the sampling site near the fyke-nets in the upper estuary, and 577 from the lower estuary. Myxozoan infection was found in a total of 61 oligochaetes, with the parasites’ developmental stages being located either in the intestinal epithelium or in the coelomic cavity. The actinospores and developmental stages occurring in the intestinal epithelium belonged to the aurantiactinomyxon (4 types), synactinomyxon (2 types) and naebia (1 type) collective groups. The actinosporean stages developing in the coelomic cavity were all identified as belonging to the sphaeractinomyxon collective group and are reported here.

In total, six different types of sphaeractinomyxon could be distinguished: four constitute new types that are described here, while the other two are known types recorded for the first time in the study area. Identification and characterisation of these types was based on both the morphological traits of mature actinospores (whenever present in the infected oligochaete) and sequences of the SSU rRNA gene. Young developmental stages could only be identified based on molecular data. Overall prevalence of infection of sphaeractinomyxon in the Minho River estuary was determined to be 0.2% (10 infected in a total of 4,593 oligochaetes examined); 0.1% in the upper estuary (5 infected in a total of 4,016 oligochaetes examined); and 0.9% in the lower estuary (5 infected in a total of 577 oligochaetes examined).

Infected oligochaetes were identified through the combined analysis of morphological features and molecular data of the 16S mitochondrial DNA (mtDNA). In the upper estuary, the freshwater “tubificoid naidids” Limnodrilus hoffmeisteri Claparède, Ilyodrilus templetoni (Southern), Psammaryctides barbatus (Grube), and Potamothenix sp. were identified as the species hosting myxozoan infection. In the lower estuary, only the marine oligochaete Tubificoides pseudogaster (Dahl) was found to be infected. Infection by sphaeractinomyxon, specifically, was determined in specimens of P. barbatus (1 type), Potamothenix sp. (2 types), and T. pseudogaster (3 types). Only one of the infected oligochaetes in the upper estuary could not be identified, because it was immature and died in the well plate, showing clear signs of degradation.

Characterisation of four novel sphaeractinomyxon types (Cnidaria: Myxozoa)

Sphaeractinomyxon type 1

Figs. 1A–D, 3A,B

Description: Mature actinospores spherical in apical view and ellipsoidal in lateral view, 26.0 ± 1.1 (24–28) long (n = 6), 25.0 ± 1.4 (22–27) wide (n = 8), 24.3 ± 0.7 (23–25) in diameter (n = 6). Some actinospores exhibited swellings located laterally in three regions equidistant apart. At centre, three polar capsules, pyriform and symmetric, 5.5 ± 0.5 (4.8–6.2) long (n = 10) and 4.1 ± 0.3 (3.6–4.7) wide (n = 23). Polar tubules with 5 longitudinal coils. Sporoplasm with hundreds of secondary cells.
Rocha et al.: Characterisation of sphaeractinomyxon and demise of endocapsa

Host: Unidentified.
Locality: The upper estuary of the Minho River, near Vila Nova de Cerveira, Portugal.
Site of infection: Throughout coelomic cavity.
Prevalence: 0.02% (1 infected of a total of 4,016 oligochaetes examined from the sampling site in the upper estuary).
Deposition of material: One glass slide of the hapantotype deposited in the Type Material Collection of the Laboratory of Animal Pathology, Interdisciplinary Centre of Marine and Environmental Research, Porto, Portugal, reference CIIMAR 2019.48.

Molecular data: One SSU rRNA gene sequence of 2,005 bp long, assembled from the identical partial sequences obtained from the parasitic material in the coelomic cavity of a single infected specimen, and deposited in GenBank with the accession no. MK418446.

Remarks: Morphometry was determined from mature actinospores observed in a single infected host. Morphological comparison revealed no gross similarity to sphaeractinomyxon types that have no available molecular data, i.e., S. stolci Caulery and Mesnil, 1904, S. gigas Granata, 1923, S. danicae Georjevitch, 1938, S. ilyodrili Jírovec, 1940, S. amanieui Puytorac, 1963, and S. rotundum Marques, 1984, Sphaeractinomyxon type 3 reported in this study (MK418448) (95%), and Sphaeractinomyxon type 2 of Rocha et al. (2019a) (MH017877) (95%). All others presented similarity values lower than 95%, including the Endocapsa of Székely et al. (2007) (DQ473516) (94%) and E. rosulata (AF306791) (89%).

Sphaeractinomyxon type 2

Description: Mature actinospores spherical in apical view and ellipsoidal in lateral view, 45.0 ± 1.1 (43‒46) long (n = 6), 54.0 ± 2.1 (51‒57) wide (n = 6), and 53.0 ± 4.2 (48‒58) in diameter (n = 6). At centre, three polar capsules, pyriform and symmetric, 9.4 ± 0.6 (8.6‒11.0) long (n = 13) and 8.2 ± 0.3 (7.8‒8.7) wide (n = 25). Polar tubules with undetermined number of coils. Sporoplasm with hundreds of secondary cells. Sporocyst with hundreds of secondary cells.
Host: Psammoryctides barbatus (Grube) (Annelida, Oligochaeta).
Locality: The upper estuary of the Minho River, near Vila Nova de Cerveira, Portugal.
Site of infection: Throughout the coelomic cavity.
Prevalence: 0.05% (2 infected of a total of 4,016 oligochaetes examined from the sampling site in the upper estuary).
Deposition of material: Series of phototypes of the hapantotype deposited together with a representative DNA sample in the Type Material Collection of the Laboratory of Animal Pathology, Interdisciplinary Centre of Marine and Environmental Research, Porto, Portugal, reference CIIMAR 2019.49.

Molecular data: One SSU rRNA gene sequence 2,002 bp
Fig. 2. Light micrographs of new types of sphaeractinomyxon infecting oligochaetes in the Minho River estuary. A–E – Sphaeractinomyxon type 3 found infecting an unidentified Potamothenax sp. in the upper estuary: developmental stages as observed within the coelomic cavity (A) and outside the host’s body (B); group of actinospores (C); immature actinospores displaying valvular swellings (D, E); F–I – Sphaeractinomyxon type 4 infecting Tubificoides pseudogaster (Dahl) in the lower estuary: developmental stages in the coelomic cavity (F); group of actinospores as observed after rupture of the pansporocyst (G); mature actinospores in apical view (H); mature actinospore in lateral view (I).

Remarks: Morphometry was determined from one of the two infected hosts, in which fully matured actinospores could be measured. Morphological comparison revealed no gross similarity to sphaeractinomyxon and endocapsa types for which there are no available molecular data. The SSU rDNA sequence did not match any sequence currently available for myxozoans, being most similar to those comprising the clade of mugiliform-infecting myxobolids (Fig. 5). Distance estimation revealed the highest percentage of similarity to Myxobolus sp. reported from the gills, intestine and tail of M. cephalus from the Mediterranean Sea off northern Israel (MF118765) (95%); all others presented similarity values lower than 95%. The actinosporean type determined to be genetically most similar (94%) to the one in study was the Sphaeractinomyxon type 9 of Rangel et al. (2016) (KU569318).
**Fig. 3.** Schematic drawings depicting mature actinospores of the new types of sphaeractinomyxon found in the coelomic cavity of freshwater and marine oligochaetes in the estuary of the Minho River, as observed in apical (left) and lateral (right) view. **A** – Sphaeractinomyxon type 1, actinospores without valvular swellings; **B** – Sphaeractinomyxon type 1, actinospores displaying valvular swellings; **C** – Sphaeractinomyxon type 2; **D** – Sphaeractinomyxon type 3; **E** – Sphaeractinomyxon type 4.

**Sphaeractinomyxon type 3**

**Description:** Mature actinospores spherical to angular in apical view and subspherical in lateral view, 21.0 ± 1.0 (19–23) long (n = 25), 21.3 ± 0.8 (20–23) wide (n = 25), and 22.0 ± 1.2 (19–24) in diameter (n = 20). A centre, three polar capsules, pyriform and symmetric, 4.8 ± 0.4 (4.1–5.5) long (n = 25) and 3.6 ± 0.2 (3.2–4) wide (n = 25). Polar tubules with 4 longitudinal coils. Sporoplasm with hundreds of secondary cells.

**Host:** Unidentified “tubificoid naidid” of the genus *Potamo-therix* Vejdovský et Mrázek (Annelida, Oligochaeta).

**Locality:** The upper estuary of the Minho River, near Vila Nova de Cerveira, Portugal.

**Site of infection:** Throughout coelomic cavity.

**Prevalence:** 0.02% (1 infected of a total of 4,016 oligochaetes examined from the sampling site in the upper estuary).

**Deposition of material:** Series of phototypes of the hapantotype deposited together with a representative DNA sample in the Type Material Collection of the Laboratory of Animal Pathology, Interdisciplinary Centre of Marine and Environmental Research, Porto, Portugal, reference CIIMAR 2019.50.

**Molecular data:** One SSU rRNA gene sequence 1,971 bp long, assembled from the identical partial sequences obtained from the parasitic material in the coelomic cavity of a single infected specimen, and deposited in GenBank with the accession no. MK418448.
Fig. 4. Light micrographs of the known types of sphaeractinomyxon found infecting *Tubificoides pseudogaster* (Dahl) in the lower estuary of the Minho River. A–C – Sphaeractinomyxon type 8 of Rangel et al. (2016a): developmental stages in the coelomic cavity (A); pansporocyst showing three mature actinospores in lateral view (B); mature actinospore in apical view (C); D–F – Sphaeractinomyxon type 10 of Rangel et al. (2016a): pansporocyst containing eight mature actinospores (D); mature actinospores in lateral view (E); and mature actinospore in apical view (F).

**Remarks:** Morphometry was determined from mature actinospores observed in a single infected host. Morphological comparison to sphaeractinomyxon and endocapsa types for which there are no available molecular data revealed some morphometric similarity to *S. leptocapsula*. The latter, however, differs from the type described here in the triangular shape of its actinospores (see Hallett et al. 1999). The sequence obtained for the parasite did not match any of the SSU rDNA sequences currently available for myxozoans, being most similar to those comprising the clade of mugiliform-infecting myxobolids (Fig. 5). Distance estimation revealed highest percentage of similarity (99%) to *Myxobolus* sp. reported from the gills, intestine and tail of *M. cephalus* from the Mediterranean Sea off northern Israel (MF118765), and to the Sphaeractinomyxon type 1 reported in this study (MK418446) (96%). All others presented similarity values lower than 95%.

**Sphaeractinomyxon type 4**

**Figs. 2F–I, 3E**

**Description:** Mature actinospores triangular in apical view and ellipsoidal in lateral view, 16.4 ± 0.8 (15–18) long (*n* = 25), 20.0 ± 0.7 (19–21) wide (*n* = 25), and 20.0 ± 0.6 (19–21) in diameter (*n* = 25). At centre, three polar capsules, pyriform and symmetric, 4.5 ± 0.4 (4.0–5.3) long (*n* = 25) and 3.2 ± 0.2 (3–3.3) wide (*n* = 25). Polar tubules with 3 to 4 longitudinal coils. Sporoplasm with hundreds of secondary cells.

**Hosts:** Unidentified tubificoid naidid of the genus *Potamothis* Vejdovský et Mrazek (Annelida, Oligochaeta), and *Tubificoides pseudogaster* (Annelida, Oligochaeta).

**Locality:** The Minho River; upper estuary near Vila Nova de Cerveira and lower estuary near Caminha, Portugal.

**Site of infection:** Throughout coelomic cavity.

**Prevalence:** Overall prevalence of infection 0.04% (2 infected of a total of 4,593 oligochaetes examined from the Minho River estuary): 0.02% in the upper estuary (1 infected in a total of 4,016 oligochaetes examined); 0.2% in the lower estuary (1 infected in a total of 577 oligochaetes examined).

**Deposition of material:** Series of phototypes of the hapantotype deposited together with a representative DNA sample in the Type Material Collection of the Laboratory of Animal Pathology, Interdisciplinary Centre of Marine and Environmental Research, Porto, Portugal, reference CIIMAR 2019.51.

**Molecular data:** One SSU rDNA sequence 2,025 bp long, representative of two identical sequences separately obtained from the parasitic material in the coelomic cavity of two infected specimens, and deposited in GenBank with the accession no. MK418449.

**Remarks:** Morphometry was determined from one of the two infected hosts (*T. pseudogaster*), in which fully matured actinospores could be measured. Morphological comparison revealed no gross similarity to sphaeractinomyxon and endocapsa types for which there are no available molecular data. The sequence obtained for the parasite did not match any of the SSU rDNA sequences currently available for myxozoans, being most similar to those comprising the clade of mugiliform-infecting myxobolids (Fig. 5). Distance estimation revealed highest percentage of similarity to (99%) *Myxobolus* sp. reported from the gills, intestine and tail of *M. cephalus* from the Mediterranean Sea.
Fig. 5. Tree topology resulting from the maximum likelihood analysis of the SSU rDNA sequences of 62 selected myxosporeans, rooted to *Myxidium lieberkuhni* (Bütschli, 1882). Numbers at the nodes represent ML bootstrap values/BI posterior probabilities/MP bootstrap values; asterisks represent full support in all methodologies; dashes represent poorly resolved nodes or a different branching pattern. New SSU rDNA sequences are in bold; SSU rDNA sequences of the former Endocapsa are underlined.
off northern Israel (MF118765); all others presented similarity values lower than 95%. This actinosporean type was genetically most similar to Sphaeractinomyxon type 1 also reported here (MK418446) (95%).

Record of two previously known sphaeractinomyxon types

Sphaeractinomyxon type 8 of Rangel et al. (2016)

Description: Mature actinospores spherical in apical and lateral view, 18.0 ± 0.3 (18–19) long (n = 25), 19.0 ± 0.5 (18–20) wide (n = 25), and 19.0 ± 0.3 (19–20) in diameter (n = 25). At centre, three polar capsules, pyriform and symmetric, 4.3 ± 0.4 (3–5) long (n = 25) and 3.1 ± 0.2 (2.9–3.2) wide (n = 25). Polar tubules with 2 to 3 longitudinal coils. Sporoplasm with hundreds of secondary cells.

Host: Tubificoides pseudogaster (Annelida, Oligochaeta).

Localities: Aveiro estuary (40°40’N; 08°45’W), lower estuary of the Minho River near Caminha (new locality); both in Portugal.

Site of infection: Throughout coelomic cavity.

Prevalence: 0.2% (1 infected of a total of 577 oligochaetes examined from the sampling site in the lower estuary).

Remarks: The SSU rDNA gene sequence obtained for the sample was 1,959 bp long and was identical with that available for Sphaeractinomyxon type 8 of Rangel et al. (2016) from its original description in the coelomic cavity of T. pseudogaster collected from the Aveiro estuary, Portugal. Significant morphometric variation was not recorded in relation to the original description (see Rangel et al. 2016).

Sphaeractinomyxon type 10 of Rangel et al. (2016)

Description: Mature actinospores spherical in apical view and ellipsoidal in lateral view, 23.0 ± 0.7 (21–24) long (n = 26), 26.0 ± 0.7 (25–27) wide (n = 26), and 26.0 ± 0.6 (25–27) in diameter (n = 30). At centre, three polar capsules, pyriform and symmetric, 4.8 ± 0.2 (4.7–5.3) long (n = 24) and 3.6 ± 0.2 (3.3–4.0) wide (n = 30). Polar tubules with 3 longitudinal coils. Sporoplasm with hundreds of secondary cells.

Hosts: Tubificoides pseudogaster (Annelida, Oligochaeta), and Tubificoides insularis (Stephenson) (Annelida, Oligochaeta).

Localities: Aveiro estuary (40°40’N; 08°45’W), Alvor estuary near the Algarve Atlantic coast (37°08’N; 08°37’W), lower estuary of the Minho River near Caminha (new locality); all in Portugal.

Site of infection: Throughout coelomic cavity.

Prevalence: 0.5% (3 infected of a total of 577 oligochaetes examined from the sampling site in the lower estuary).

Remarks: The SSU rDNA sequences obtained for this type in three infected host specimens were ~2,010 bp long. They were identical with the sequence available for Sphaeractinomyxon type 10 of Rangel et al. (2016) from its original description in the coelomic cavity of the same host, T. pseudogaster, in the Aveiro estuary, Portugal. Significant morphometric variation was not recorded in relation to the original description of this type, nor to its report from T. insularis in the Alvor estuary, near the Algarve Atlantic coast (see Rangel et al. 2016, Rocha et al. 2019a).

Phylogenetic analyses

ML, BI and MP analyses produced similar tree topologies and revealed all new SSU rDNA sequences obtained in this study clustering within the clade of mugiliform-infecting myxobolids (Fig. 5), alongside all Myxobolus spp. thus far reported from mullet hosts, as well as all other types of the sphaeractinomyxon and endocapsa collective groups with available molecular data. The Triactinomyxon type of Székely et al. (2007) (DQ473515) was also positioned within this clade.

DISCUSSION

In this study, actinosporean infection by members of the sphaeractinomyxon collective group was found in the coelomic cavity of both freshwater and marine oligochaetes inhabiting the Minho River estuary. Four new types are described here, whereas two others were identified as being Sphaeractinomyxon types 8 and 10 of Rangel et al. (2016). These two latter types were originally described from specimens of Tubificoides pseudogaster collected from the Aveiro estuary (Portugal) (Rangel et al. 2016), about 180 km south from our sampling location in the Minho River. The Sphaeractinomyxon type 10 of Rangel et al. (2016) was also reported from a wetland system in the Western Algarve (see Rocha et al. 2019b), which is located about 700 km south from our sampling location.

The application of molecular tools to the study of actinosporean stages has revealed that the morphological characterisation of actinospores is important but insufficient for the description of new types (see Halliet et al. 2002, 2004, Esztetbauer et al. 2006). In the case of sphaeractinomyxon, studies show that actinospore measurements overlap between molecularly different types that may occur in the same oligochaete host species (see Rangel et al. 2016).

As such, the new and known types reported here were described using a combination of morphological and molecular data. Although the actinospores of the four new types differed amongst each other in their overall morphology, a high morphological similarity was found between the actinospores of the new Sphaeractinomyxon type 4 and those of the Sphaeractinomyxon type 8 of Rangel et al. (2016) (Table 1). Both these types were observed developing in the coelomic cavity of specimens of T. pseudogaster collected from the lower estuary of the Minho River and, therefore, could only be distinguished through comparison of their respective SSU rDNA sequences. Consequently, our results strengthen the contention that the acquisition of molecular information is indispensable for both the characterisation of new types and proper identification of known types.

Oligochaete hosts were also identified through the combined analysis of morphological traits and molecular information of the 16S locus. Recognition at the species-level, however, was only achieved for the freshwater oligochaete Psammoryctides barbatus, identified as the host of Sphaeractinomyxon type 2 in the upper estuary, and the marine oligochaete T. pseudogaster, identified as the host of the new Sphaeractinomyxon type 4 and Sphaeractinomyxon types 8 and 10 of Rangel et al. (2016) in the lower estuary.
In contrast, the oligochaete hosts of Sphaeractinomyxon types 3 and 4 in the upper estuary could only be recognised as belonging to the same unidentified species of the genus Potamothrix. Lastly, it was not possible to morphologically and molecularly identify the oligochaete species infected with Sphaeractinomyxon type 1, because the specimen in question was immature and died in the well plate, showing clear signs of degradation.

Despite more than one type being registered here from the same Potamothrix sp. in the upper estuary, as well from T. pseudogaster in the lower estuary, mixed infections were not observed. This is congruent with previous studies that reported several different actinosporean types from a single oligochaete species, but never taking place simultaneously in the same individual (e.g., El-Mansy et al. 1998, Xi et al. 2013, 2015, Rosser et al. 2014). In fact, a considerable diversity of sphaeractinomyxon types have been reported to infect T. pseudogaster, Tubificoides insularis and Limnodriloides agnes Hrabě in Portuguese estuaries, but concomitant infections were never recorded (see Rangel et al. 2016, Rocha et al. 2019a).

Of the 25 types of sphaeractinomyxon described in the literature, only four have been reported to infect oligochaetes associated with freshwater environments: S. danicae from an Eiseniella sp., probably E. tetraedra (Savigny); S. gigas from Limnodrilus hoffmeisteri; S. ilyodrili from Potamothrix prespaensis (Hrabě); and S. rotundum from unidentified tubificids at Latour-bas-Eline and Villeneuve de la Raho, France (Marques 1984). Our study considerably increases the number of sphaeractinomyxon reported from freshwater and further suggests susceptibility of Potamothrix spp. to infection by sphaeractinomyxon.

In brackish/marine environments, species of the genera Tubificoides Lastočkin and Limnodriloides Pierantoni appear to be the more susceptible to infection by sphaeractinomyxon, thus far having been each recognised as hosts for seven different types of this collective group in Portuguese estuaries (see Rangel et al. 2016, Rocha et al. 2019a). Nonetheless, myxozoan surveys targeting brackish/marine invertebrate communities in other geographic locations may reveal other susceptible oligochaete taxa.

Most sphaeractinomyxon types have been reported exclusively from a single host species. Until this study, Sphaeractinomyxon type 10 of Rangel et al. (2016) constituted the only confirmed exception to a strict host specificity of the collective group with molecular evidence of its development in the coelomic cavity of both T. pseudogaster and T. insularis (see Rocha et al. 2019a). Although Sphaeractinomyxon stolci and Sphaeractinomyxon ersei were also reported from more than one oligochaete species, their identification in different hosts was based solely on morphological criteria and, therefore, remains uncertain. As such, the occurrence of Sphaeractinomyxon type 4 in two distinct oligochaete species of the family Naididae Ehrenberg, more specifically in a freshwater Potamothrix sp. inhabiting the upper estuary and in the marine oligochaete T. pseudogaster inhabiting the lower estuary, confirms that sphaeractinomyxon types are not necessarily restricted to a single host species. Moreover, the presence of this type in both a freshwater and a brackish habitat reinforces the potential involvement of the sphaeractinomyxon collective group in the life cycle of myxosporian species that infect migratory fish hosts, probably mullets, as hypothesised by Rocha et al. (2019b).

Holzer et al. (2018) showed that myxozoans diversified massively after entering fish as second hosts, given that the acquisition of this vertebrate group enabled alternative transmission and dispersion strategies that were crucial in the conquest of new habitats. Mullets are catadromous, meaning that they are born in saltwater and then migrate into freshwater, where they grow before returning to the ocean to spawn. In coastal and estuarine ecosystems, where these fishes spend a considerable portion of their lives, a zonal distribution of species has been shown to occur according to salinity gradients. Some species, such as the thinlip grey mullet Chelon ramada (Risso), have a higher adaptability to low salinities and water pollution, thus being able to migrate into the upper estuary (Torriceilli et al. 1981, Cardona 2006).

In this context, it can be hypothesised that the acquisition of mullets as second hosts would have allowed the myxosporian counterparts of sphaeractinomyxon to potentially cross environmental barriers and conquer new habitats, whenever a susceptible host could be found in the invertebrate community. The presence of Sphaeractinomyxon type 10 of Rangel et al. (2016) in three Portuguese estuaries (Rangel et al. 2016, Rocha et al. 2019a) further corroborates the crucial role of the vertebrate host in the geographic dissemination of myxosporan parasites.

Individual values of prevalence of infection were determined to be lower than 1% for all types reported here. These values are in accordance with those reported in previous studies for other types of sphaeractinomyxon, as well as for types of other actinosporean collective groups.

SL – actinospore length in lateral view; SW – actinospore width in lateral view; SD – actinospore diameter in apical view; PCL – polar capsule length; PCW – polar capsule width; PTc – number of polar tube coils. Measurements are means ± SD (range), given in μm.
(e.g., Hallett et al. 1999, Székely et al. 2007, Xi et al. 2015, Rocha et al. 2019b). In turn, the overall prevalence of infection of sphaeractinomyxon determined in this study was significantly lower than that reported in previous myxozoan surveys of Portuguese estuaries (see Rangel et al. 2016, Rocha et al. 2019a), which can be correlated to the sampling sites that were chosen in the Minho River.

Other studies collected oligochaetes solely from lower estuaries, while our efforts were divided between two sampling sites, one of which was located in freshwater. Indeed, overall prevalence of infection was noted to be significantly higher in the lower estuary than in the upper estuary, which is consistent with the involvement of sphaeractinomyxon in the life cycles of migratory fish hosts. As previously mentioned, migratory fish spend considerable portions of their lives in brackish environments and, therefore, are more prone to acquire myxozoan infection from the invertebrate communities settled in the lower estuaries.

Thus, further sampling of oligochaetes from the lower estuary of the Minho River will probably reveal a higher diversity of the sphaeractinomyxon collective group. Considering that the sphaeractinomyxon types described here are expected to be counterparts in the life cycles of myxosporean parasites, future research in the Minho River and other Portuguese estuaries should also aim to sample potential fish hosts, namely mullets. To date, Myxobolus exiguis Thélohan, 1895 constitutes the only myxosporean parasite that has been reported from the Minho River, more specifically from the visceral peritoneum of the thin-lip grey mullet C. ramada (Rocha et al. 2019b).

The phylogenetic analysis performed in this study showed the new types described here, both freshwater and marine, clustering alongside all other members of the sphaeractinomyxon collective group within the mugiliform-infecting clade of myxobolids (Fig. 5), in accordance with the study of Rocha et al. (2019a). Following the demise of the tetraspora collective group and reassignment of its types to sphaeractinomyxon, only three other actinosporean stages cluster within this mugiliform-infecting clade: Endocapsa rosulata, Endocapsa of Székely et al. (2007), and Triactinomyxon of Székely et al. (2007).

The endocapsa collective group was erected to encompass actinospores that differ morphologically from sphaeractinomyxon only by having irregular processes in the form of swellings that do not change when in contact with water (Hallett et al. 1999). The microscopic observations performed in this study, however, revealed the presence of actinospores with and without valvular swellings in the coelomic cavity of the oligochaete host displaying infection by the new Sphaeractinomyxon type 1. Therefore, casts doubts upon the validity of this morphological criterion for distinguishing between sphaeractinomyxon and endocapsa. Immature actinospores displaying valvular swellings were further observed as part of the development of the other types described here (see Fig. 2D,E). This is congruent with the observations of Rangel et al. (2016), who reported immature sphaeractinomyxon actinospores often displaying valvular swellings similar to those described for endocapsa. These authors also acknowledged that dehydration of mature actinospores caused the sporoplasm to concentrate centrally, leading to the formation of swellings.

A more in-depth look at the available literature further evidences the tenuous distinction between the sphaeractinomyxon and endocapsa collective groups. For instance, Hallett et al. (1999) reported actinospores reminiscent of the original type, Endocapsa rosulata, but without valvular swellings (typical sphaeractinomyxon by default), developing in oligochaetes collected from the same locality. Similarly, the single lobe-like swelling of Endocapsa stepheni was reported to be visible in some actinospores in situ (Hallett et al. 1999). Overall, the figures provided in the description of Endocapsa of Székely et al. (2007) show degradation of the actinospores and, therefore, do not give support to the group. Actinospores of Sphaeractinomyxon gigas were reported to form a double trigonal pyramid, with rounded faces, which can be part of an ellipse (Marques 1984).

Thus, it can be stated that the presence/absence of valvular swellings in the actinospores constitutes a morphological character unsuitable for differentiation between sphaeractinomyxon and endocapsa. The existence of the endocapsa collective group is further questioned by phylogenetic analyses of the SSU rRNA gene which, similarly to the ones performed in this study, show all endocapsa and sphaeractinomyxon types with available molecular data consistently clustering together within a myxobolid clade previously suggested to have a monophyletic origin (Rocha et al., 2019a, b).

Considering all the above, we suggest that endocapsa be deemed invalid and its types transferred to sphaeractinomyxon: E. rosulata becomes Sphaeractinomyxon type 1 of Hallett et al. (1999), E. stepheni becomes Sphaeractinomyxon type 2 of Hallett et al. (1999), Endocapsa type of Hallett et al. (2001) becomes Sphaeractinomyxon type of Hallett et al. (2001), and Endocapsa type of Székely et al. (2007) becomes Sphaeractinomyxon type of Székely et al. (2007).

The evolution of myxozoans and their invertebrate hosts has been shown to be highly congruent, namely because oligochaetes and polychaetes are the definitive and most ancient hosts of this parasitic group (Holzer et al. 2018). As such, future comprehensive revisions of some actinosporean collective groups may be necessary in order to more accurately reflect current phylogenetic and morphological information.
