Abstract: The eye nematode *Thelazia callipaeda* Railliet et Henry, 1910 (Spirurida: Thelaziidae) is a vector-borne zoonotic nematode infecting a range of wild and domestic carnivores as well as humans. It is considered to be a causative agent of emerging and neglected disease and currently invades central part of Europe. Nematodes were collected from the eye of a dog living in Prague, which never travelled outside the Czech Republic. The nematodes were identified based on their morphology and partial sequence of the *cox1* gene as *T. callipaeda* haplotype 1. This finding represents the northernmost record of autochthonous canine thelaziosis in Europe. The insufficient control of imported animals as well as free movement of dogs and wild carnivores within Europe probably facilitates spreading of *T. callipaeda* throughout the continent. To better understand the spreading of *T. callipaeda* and to prevent its zoonotic transmissions, information about the risk of this infection in newly invaded countries should be disseminated not only among veterinarians and physicians, but also within the community of pet owners and hunters.

Keywords: Europe, carnivora, Czech Republic, dog, vector-borne disease

The canine eye-worm, *Thelazia callipaeda* Railliet et Henry, 1910 (Spirurida: Thelaziidae), is a vector-borne zoonotic nematode infecting a range of wild and domestic carnivores, rarely lagomorphs as well as humans (Otranto et al. 2015, Colella et al. 2016, Gama et al. 2016, Mihalca et al. 2016, Ioncă et al. 2019). *Thelazia callipaeda* is known as the ‘oriental eye-worm’ as it infects primarily dogs in countries of the Far East, where it is also a concern of public health (Colella et al. 2016). Within the last two decades, *T. callipaeda* has been frequently reported in carnivores and occasionally also in humans in several European countries. Its fast spreading throughout Europe is a prominent example of biological invasion (Otranto and Dantas-Torres 2015), Colella et al. 2016). Within the last two decades, *T. callipaeda* has been frequently reported in carnivores and occasionally also in humans in several European countries. Its fast spreading throughout Europe is a prominent example of biological invasion (Otranto and Dantas-Torres 2015). The life cycle of *T. callipaeda* is indirect and involves a non-biting Diptera as an intermediate host, in Europe represented only by the fruit fly *Amiota variegata* (Fallén, 1823) (*Drosophilidae* (Otranto et al. 2006). The insect vector transmits the third-stage (L3) larvae while feeding on ocular secretions of receptive vertebrate definitive hosts (carnivores or humans). The adult nematodes remain localised in the host’s eye, producing the first stage (L1) larvae that are eventually ingested by the insect host and develop into L3 larvae, closing the nematode’s life cycle. In de-
finitive hosts, adults are commonly found under the lids and nictitating membrane as well as in conjunctival sacs (Otranto et al. 2015). Thus, clinical signs of thelaziosis involve conjunctivitis, epiphora, ocular discharge (often purulent), lacrimation, corneal edema to keratitis or even corneal ulceration (Otranto et al. 2015).

Treatment of thelaziosis is currently based on the manual removal of nematodes directly from the eye of affected dogs, under local anesthesia, and supplemented by an application of spot-on or also oral formulas containing active substances such as imidacloprid, moxidectin or milbemycin (Otranto et al. 2016, Lebon et al. 2019).

The present report describes the occurrence of autochthonous canine thelaziosis in the Czech Republic based on morphological and molecular identification.

MATERIALS AND METHODS

In July 2018, a six-year-old male border collie was admitted for consultation at the Veterinary Clinic Lhotka (Prague 4, Czech Republic) with the unilateral purulent discharge from the right eye. Before this visit, the problem persisted for two weeks when the owner administered boric acid for eye treatment. The dog’s orientation and behaviour as well as the pupillary reflex were normal. The fluorescein test was performed. During a closer inspection of the affected eye, 10–15 mm long nematodes were found under the third lid, which were moving and twisting into a spiral.

Collected nematodes were fixed by hot water and preserved in absolute ethanol for morphological and molecular analyses. For light microscopy examination, the nematodes were cleared with glycerin and studied as temporary slides. Microphotographs were taken using a drawing attachment on an Olympus BX51 microscope (Olympus Corporation, Tokyo, Japan) with differential interference contrast optics. For morphological identification, three worms (one male and two females) which were collected during the first visit of the clinic were used. Identification was done according to the morphological features reported by Skrjabin et al. (1967).

For molecular identification, the total DNA was extracted from one adult worm using 200 µl of 5% Chelex® 100 sodium form (Sigma-Aldrich, St. Louis, Missouri, USA), incubated at 60°C for 1 hr, and then boiled at 90°C for 20 min, and stored at 4°C. PCR amplification of partial cytochrome c oxidase subunit 1 gene (cox1) was performed as described in Folmer et al. (1994) and the product was Sanger-sequenced in GATC Biotech (Konstanz, Germany).
many). Quality of the sequence was checked, the cox1 sequence was trimmed and subsequently aligned to the representatives of Thelazia callipaeda downloaded from GenBank using Geneious 7.1.9 (http://www.geneious.com). The new sequence was submitted to the GenBank database under accession No. MN310555.

RESULTS
In total, seven adult nematodes were collected from the dog’s affected eye during all visits at the Veterinary Clinic Lhotka in 2018 (Fig. 1). The left eye was without any clinical signs. The affected eye showed catarrhal-purulent discharge and mildly irritated conjunctiva, without blepharospasm or any further pathological findings. The fluorescein test revealed no corneal ulceration. Adult nematodes were removed from the affected eye under local (using procaine) and later also general anesthesia during three visits of the clinic (during July 2018). Then, the dog remained negative during two other consultations at the clinic (in August 2018 and a half year later).

The recent history of the dog, as recalled by the owner, did not include any travel outside the Czech Republic. However, owner reported occasional travels in and around Prague (approx. 50°05’N; 14°25’E), its surroundings (the Central Bohemia), and in the North-West Bohemia, the Elbe lowland area (specifically Litoměřice area, approx. 50°32’N; 14°7’55’E) (Fig. 2). The present record of canine

*A—autochthonous; I—imported

Table 1.

In the past decade there has been a progressive and probably also accelerating invasion of *Thelazia callipaeida* in the wild and domestic carnivores, which also poses a risk of infection for humans (Otranto and Dantas-Torres 2015). This nematode was apparently imported from Asia to the southern or southeastern Europe towards northwest (Table 1), and it is likely facilitated by common occurrence of its drosophilid vector, *Amiota variegata* (see Otranto et al. 2006).

The present report describes an autochthonous case of the canine infection with *T. callipaeida* in the Czech Republic. Along with the other reports on its occurrence from neighbouring countries, specifically Germany, Austria and Slovakia (Magnis et al. 2010, Čabanova et al. 2017, Hodžič et al. 2019), it is evident that populations of *T. callipaeida* are already established in Central Europe, probably following its spread through southern Europe and the Balkan area (Otranto and Dantas-Torres 2015, Colella et al. 2016) (Table 1).

Given the fact that the infected dog in our study did not have a history of travelling to foreign endemic areas, we consider this to be a sufficient evidence of the autochthonous occurrence of *T. callipaeida* in the Czech Republic. The recent report by Hofmannová et al. (2019) briefly describes two other cases of canine thelaziosis in the Czech Republic recorded in 2017 and 2018, but without molecular and morphological data. It documents another case of the autochthonous infection of *T. callipaeida* in a dachshund and also probably imported case of canine thelaziosis in South Bohemia. The latter crossbreed dog had a clear history of traveling to the endemic area of Bulgaria in autumn 2016 (Colella et al. 2016), and later the clinical thelaziosis was diagnosed in winter 2016/2017.

The nematodes obtained from the dog’s eye in this study were morphologically and genetically identical with *T. callipaeida*. In general, *T. callipaeida* shows a high genetic diversity across its original range in eastern Asia, with approximately 20 haplotypes determined so far (Zhang et al. 2018). Contrary to this fact, only haplotype 1 is reported from different European localities, suggesting a single invasion event. Our analysis of a partial sequence of cox1 demonstrates the haplotype 1 as described previously (Otranto et al. 2005, Mihalca et al. 2015). Unfortunately, the previously described cases of *T. callipaeida* in the Czech Republic are not molecularly classified (Hofmannová et al. 2019).

The vector of *T. callipaeida*, *A. variegata*, is broadly distributed across Europe throughout forested areas with deciduous forests (Otranto et al. 2006). Retrospective evaluation of the dog’s movement involved in both autochthonous cases of thelaziosis in the Czech Republic placed a likely origin of these infections to lowland areas of the Central and North-West Bohemia (Fig. 2). The environmental conditions of these areas (i.e., 136–399 metres of altitude, ca. 50% relative humidity, average daily summer temperature 24°C) together with the presence of deciduous forests correspond well with the occurrence of *A. variegata* in Europe (Palfreyman et al. 2018).

The infection of *T. callipaeida* in the dog from Prague and its clinical manifestation was recorded in the warmest period of the year, when potential intermediate hosts are most available (Otranto et al. 2006, 2015). The prepatent period of *T. callipaeida* takes about one month (Otranto et al. 2019).
et al. 2004). Based on this, we assume that infection of the dog from Prague was acquired during spring 2018. For the dog’s therapy, the spot-on formulation Advantix® containing a combination of imidacloprid and permethrin was used with regard to the breed predisposition of border collies to MDR1 gene mutation. In this case a use of milbemycin, which is in all recommended therapies for thelaziosis in dogs, is contraindicated (Geyer and Janko 2012).

Despite the increasing number of cases of T. callipeda infections in domestic and wild animals across Europe, the pathways of spreading of this vector-borne parasitosis remain to be understood. Undoubtedly, free movement of people and their pets within the European Union is a risk factor for the translocation of various diseases and their vectors (e.g., Fooks and Johnson 2015; Gordon et al. 2016). A growing body of the literature demonstrates that wild carnivores play an important role in local epidemiology of T. callipeda, especially red foxes appear to be the most suitable reservoir hosts (Otranto and Deplazes 2019).

In addition, cases of thelaziosis were reported also among Eurasian golden jackals (Mihalca et al. 2016), which have rapidly expanded their European range and also reached the Czech Republic (Jirků et al. 2018). Although the role of mobile free-ranging carnivores such as European wolves or jackals cannot be neglected, it is probable that the major driver of the T. callipeda range expansion is the movement of dogs that travel together with their owners, as well as adoption/importation of dogs from shelters in southeastern Europe.

Acknowledgements. We are indebted to Jan Brabec and Zuzana Lhotská (Institute of Parasitology) as well as Lukáš Holly (Veterinary Clinic Lhota) who contributed to the preparation of this study.
